Abstract

Adversarial evaluation stress tests a model’s understanding of natural language. While past approaches expose superficial patterns, the resulting adversarial examples are limited in complexity and diversity. We propose human-in-the-loop adversarial generation, where human authors are guided to break models. We aid the authors with interpretations of model predictions through an interactive user interface. We apply this generation framework to a question answering task called Quizbowl, where trivia enthusiasts craft adversarial questions. The resulting questions are validated via live human–computer matches: although the questions appear ordinary to humans, they systematically stump neural and information retrieval models. The adversarial questions cover diverse phenomena from multi-hop reasoning to entity type distractors, exposing open challenges in robust question answering.

1 Introduction

Proponents of machine learning claim human parity on tasks like reading comprehension (Yu et al., 2018) and commonsense inference (Devlin et al., 2018). Despite these successes, many evaluations neglect that computers solve NLP tasks in a fundamentally different way than humans.

Models can succeed without developing “true” language understanding, instead learning superficial patterns from crawled (Chen et al., 2016) or manually annotated datasets (Kaushik and Lipton, 2018; Gururangan et al., 2018). Thus, recent work

stress tests models via adversarial evaluation: elucidating a system’s capabilities by exploiting its weaknesses (Jia and Liang, 2017; Belinkov and Glass, 2019). Unfortunately, while adversarial evaluation reveals simplistic model failures (Ribeiro et al., 2018; Mudrakarta et al., 2018), exploring more complex failure patterns requires human involvement (Figure 1): automatically modifying natural language examples without invalidating them is difficult. Hence, the diversity of adversarial examples is often severely restricted.

Instead, our human–computer hybrid approach uses human creativity to generate adversarial examples. A user interface presents model interpretations and helps users craft model-breaking examples (Section 3). We apply this to a question answering (QA) task called Quizbowl, where trivia enthusiasts—who write questions for academic competitions—create diverse examples that stump existing QA models.

The adversarially-authored test set is nonetheless easy as regular questions for humans (Section 4), but the relative accuracy of strong QA models drops as much as 40% (Section 5). We also host live human vs. computer matches, where models typically defeat top human teams, but observe spectacular model failures on adversarial questions.

Analyzing the adversarial edits uncovers phenomena that humans can solve but computers cannot (Section 6), validating that our framework uncovers creative, targeted adversarial edits (Section 7). Our resulting adversarial dataset presents a fun, challenging, and diverse resource for future QA research: a system that masters it will demonstrate more robust language understanding.
Figure 1: Adversarial evaluation in NLP typically focuses on a specific phenomenon (e.g., word replacements) and then generates the corresponding examples (top). Consequently, adversarial examples are limited to the diversity of what the underlying generative model or perturbation rule can produce, and also require downstream human evaluation to ensure validity. Our setup (bottom) instead has human-authored examples, using human–computer collaboration to craft adversarial examples with greater diversity.

2 Adversarial Evaluation for NLP

Adversarial examples (Szegedy et al., 2013) often reveal model failures better than traditional test sets. However, automatic adversarial generation is tricky for NLP (e.g., by replacing words) without changing an example’s meaning or invalidating it.

Recent work side-steps this by focusing on simple transformations that preserve meaning. For instance, Ribeiro et al. (2018) generate adversarial perturbations such as replacing What has -> What's. Other minor perturbations such as typos (Belinkov and Bisk, 2018), adding distractor sentences (Jia and Liang, 2017; Mudrakarta et al., 2018), or character replacements (Ebrahimi et al., 2018) preserve meaning while degrading model performance.

Generative models can discover more adversarial perturbations but require post-hoc human verification of the examples. For example, neural paraphrase or language models can generate syntactic modifications (Iyyer et al., 2018), plausible captions (Zellers et al., 2018), or NLI premises (Zhao et al., 2018). These methods improve example-level diversity but mainly target a specific phenomenon, e.g., rewriting question syntax.

Furthermore, existing adversarial perturbations are restricted to sentences—not the paragraph inputs of Quizbowl and other tasks—due to challenges in long-text generation. For instance, syntax paraphrase networks (Iyyer et al., 2018) applied to Quizbowl only yield valid paraphrases 3% of the time (Appendix A).

2.1 Putting a Human in the Loop

Instead, we task human authors with adversarial writing of questions: generating examples which break a specific QA system but are still answerable by humans. We expose model predictions and interpretations to question authors, who find question edits that confuse the model.

The user interface makes the adversarial writing process interactive and model-driven, in contrast to adversarial examples written independent of a model (Ettinger et al., 2017). The result is an adversarially-authored dataset that explicitly exposes a model’s limitations by design.

Human-in-the-loop generation can replace or aid model-based adversarial generation approaches. Creating interfaces and interpretations is often easier than designing and training generative models for specific domains. In domains where adversarial generation is feasible, human creativity can reveal which tactics automatic approaches can later emulate. Model-based and human-in-the-loop generation approaches can also be combined by training models to mimic human adversarial edit history, using the relative merits of both approaches.

3 Our QA Testbed: Quizbowl

The “gold standard” of academic competitions between universities and high schools is Quizbowl. Unlike QA formats such as Jeopardy! (Ferrucci et al., 2010), Quizbowl questions are designed to be interrupted: questions are read to two competing teams and whoever knows the answer first interrupts the question and “buzzes in”.

This style of play requires questions to be structured “pyramidally” (Jose, 2017): questions start with difficult clues and get progressively easier. These questions are carefully crafted to allow the most knowledgeable player to answer first. A question on Paris that begins “this capital of France” would test reaction speed, not knowledge; thus, skilled authors arrange the clues so players will recognize them with increasing probability (Figure 2).

The answers to Quizbowl questions are typically well-known entities. In the QA community (Hirschman and Gaizauskas, 2001), this is called “factoid” QA: the entities come from a relatively closed set of possible answers.
The protagonist of this opera describes the future day when her lover will arrive on a boat in the aria “Un Bel Di” or “One Beautiful Day”. The only baritone role in this opera is the consul Sharpless who reads letters for the protagonist, who has a maid named Suzuki. That protagonist blindfolds her child Sorrow before stabbing herself when her lover B. F. Pinkerton returns with a wife. For 10 points, name this Giacomo Puccini opera about an American lieutenant’s affair with the Japanese woman Cio-Cio San.

Answer: Madama Butterfly

Figure 2: An example Quizbowl question. The question becomes progressively easier (for humans) to answer later on; thus, more knowledgeable players can answer after hearing fewer clues. Our adversarial writing process ensures that the clues also challenge computers.

3.1 Known Exploits of Quizbowl Questions

Like most QA datasets, Quizbowl questions are written for humans. Unfortunately, the heuristics that question authors use to select clues do not always apply to computers. For example, humans are unlikely to memorize every song in every opera by a particular composer. This, however, is trivial for a computer. In particular, a simple QA system easily solves the example in Figure 2 from seeing the reference to “Un Bel Di”. Other questions contain uniquely identifying “trigger words” (Harris, 2006). For example, “martensite” only appears in questions on steel. For these examples, a QA system needs to understand no additional information other than an if-then rule.

One might wonder if this means that factoid QA is thus an uninteresting, nearly solved research problem. However, some Quizbowl questions are fiendishly difficult for computers. Many questions have intricate coreference patterns (Guha et al., 2015), require reasoning across multiple types of knowledge, or involve complex wordplay. If we can isolate and generate questions with these difficult phenomena, “simplistic” factoid QA quickly becomes non-trivial.

3.2 Models and Datasets

We conduct two rounds of adversarial writing. In the first, authors attack a traditional Information Retrieval (IR) system. The IR model is the baseline from a NIPS 2017 shared task on Quizbowl (Boyd-Graber et al., 2018) based on ElasticSearch (Gormley and Tong, 2015). In the second round, authors attack either the IR model or a neural QA model. The neural model is a bidirectional RNN using the gated recurrent unit architecture (Cho et al., 2014). The model treats Quizbowl as classification and predicts the answer entity from a sequence of words represented as 300-dimensional GloVe embeddings (Pennington et al., 2014). Both models in this round are trained using an expanded dataset of approximately 110,000 Quizbowl questions. We expanded the round two dataset to incorporate more diverse answers (25,000 entities versus 11,000 in round one).

3.3 Interpreting Quizbowl Models

To help write adversarial questions, we expose what the model is thinking to the authors. We interpret models using saliency heat maps: each word of the question is highlighted based on its importance to the model’s prediction (Ribeiro et al., 2016).

For the neural model, word importance is the decrease in prediction probability when a word is removed (Li et al., 2016; Wallace et al., 2018). We focus on gradient-based approximations (Simonyan et al., 2014; Montavon et al., 2017) for their computational efficiency.

To interpret a model prediction on an input sequence of n words $w = \langle w_1, w_2, \ldots, w_n \rangle$, we approximate the classifier $f$ with a linear function of $w_i$ derived from the first-order Taylor expansion. The importance of $w_i$, with embedding $v_i$, is the derivative of $f$ with respect to the one-hot vector:

$$\frac{\partial f}{\partial w_i} = \frac{\partial f}{\partial v_i} \frac{\partial v_i}{\partial w_i} = \frac{\partial f}{\partial v_i} . v_i. \tag{1}$$

This simulates how model predictions change when a particular word’s embedding is set to the zero vector, i.e., it approximates word removal (Ebrahimi et al., 2018; Wallace et al., 2018).

For the IR model, we use the ElasticSearch Highlight API (Gormley and Tong, 2015), which provides word importance scores based on query matches from the inverted index.

3.4 Adversarial Writing Interface

The authors interact with either the IR or RNN model through a user interface\(^1\) (Figure 3). An author writes their question in the upper right while the model’s top five predictions (Machine Guesses) appear in the upper left. If the top prediction is

\(^1\)https://github.com/Eric-Wallace/trickme-interface/
Figure 3: The author writes a question (top right), the QA system provides guesses (left), and explains why it makes those guesses (bottom right). The author can then adapt their question to “trick” the model.

the right answer, the interface indicates where in the question the model is first correct. The goal is to cause the model to be incorrect or to delay the correct answer position as much as possible. The words of the current question are highlighted using the applicable interpretation method in the lower right (Evidence). We do not enforce time restrictions or require questions to be adversarial: if the author fails to break the system, they are free to “give up” and submit any question.

The interface continually updates as the author writes. We track the question edit history to identify recurring model failures (Section 6) and understand how interpretations guide the authors (Section 7).

3.5 Question Authors

We focus on members of the Quizbowl community: they have deep trivia knowledge and craft questions for Quizbowl tournaments (Jennings, 2006). We award prizes for questions read at live human–computer matches (Section 5.3).

The question authors are familiar with the standard format of Quizbowl questions (Lujan and Teitler, 2003). The questions follow a common paragraph structure, are well edited for grammar, and finish with a simple “give-away” clue. These constraints benefit the adversarial writing process as it is very clear what constitutes a difficult but valid question. Thus, our examples go beyond surface level “breaks” such as character noise (Belinkov and Bisk, 2018) or syntax changes (Iyyer et al., 2018). Rather, questions are difficult because of their semantic content (examples in Section 6).

3.6 How an Author Writes a Question

To see how an author might write a question with the interface, we walk through an example of writing a question’s first sentence. The author first selects the answer to their question from the training set—Johannes Brahms—and begins:

Karl Ferdinand Pohl showed this composer some pieces on which this composer’s Variations on a Theme by Haydn were based.

The QA system buzzes (i.e., it has enough information to interrupt and answer correctly) after “composer”. The author sees that the name “Karl Ferdinand Pohl” appears in Brahms’ Wikipedia page and avoids that specific phrase, describing Pohl’s position instead of naming him directly:

This composer was given a theme called “Chorale St. Antoni” by the archivist of the Vienna Musikverein, which could have been written by Ignaz Pleyel.
This rewrite adds in some additional information (there is a scholarly disagreement over who wrote the theme and its name), and the QA system now incorrectly thinks the answer is Frédéric Chopin. The user can continue to build on the theme, writing:

> While summering in Tutzing, this composer turned that theme into “Variations on a Theme by Haydn”.

Again, the author then sees that the system buzzes “Variations on a Theme” with the correct answer. However, the author can rewrite it in its original German, “Variationen über ein Thema von Haydn” to fool the system. The author continues to create entire questions the model cannot solve.

### 4 A New Adversarially-Authored Dataset

We validate that the adversarially-authored questions are not of poor quality or too difficult for humans. We first automatically filter out questions based on length, the presence of vulgar statements, or repeated submissions (including re-submissions from the Quizbowl training or evaluation data).

We next host a human-only Quizbowl event using intermediate and expert players (former and current collegiate Quizbowl players). We select sixty adversarially-authored questions and sixty standard high school national championship questions, both with the same number of questions per category (list of categories in Table 1).

To answer a Quizbowl question, a player interrupts the question: the earlier the better. To capture this dynamic, we record both the average answer position (as a percentage of the question, lower is better) and answer accuracy. We shuffle the regular and adversarially-authored questions, read them to players, and record these two metrics.

The adversarially-authored questions are on average easier for humans than the regular test questions. For the adversarially-authored set, humans buzz with 41.6% of the question remaining and an accuracy of 89.7%. On the standard questions, humans buzz with 28.3% of the question remaining and an accuracy of 84.2%. The difference in accuracy between the two types of questions is not significantly different ($p = 0.16$ using Fisher’s exact test), but the buzzing position is earlier for adversarially-authored questions ($p = 0.0047$ for a two-sided $t$-test). We expect the questions that were not played to be of comparable difficulty because they went through the same submission process and post-processing. We further explore the human-perceived difficulty of the adversarially-authored questions in Section 5.3.

### 5 Computer Experiments

This section evaluates QA systems on the adversarially-authored questions. We test three models: the IR and RNN models shown in the interface, as well as a Deep Averaging Network (Iyyer et al., 2015, DAN) to evaluate the transferability of the adversarial questions. We break our study into two rounds. The first round consists of adversarially-authored questions written against the IR system (Section 5.1); the second round questions target both the IR and RNN (Section 5.2).

Finally, we also hold live competitions that pit the state-of-the-art Studio Ousia model (Yamada et al., 2018) against human teams (Section 5.3).

#### 5.1 First Round Attacks: IR Adversarial Questions Transfer To All Models

The first round of adversarially-authored questions target the IR model and are significantly harder for the IR, RNN, and DAN models (Figure 4). For example, the DAN’s accuracy drops from 54.1% to 32.4% on the full question (60% of original performance).

For both adversarially-authored and original test
Figure 4: The first round of adversarial writing attacks the IR model. Like regular test questions, adversarially-authored questions begin with difficult clues that trick the model. However, the adversarial questions are significantly harder during the crucial middle third of the question.

Figure 5: The second round of adversarial writing attacks the IR and RNN models. The questions targeted against the IR system degrade the performance of all models. However, the reverse does not hold: the IR model is robust to the questions written to fool the RNN.

questions, the early clues are difficult to answer (accuracy about 10% through 25% of the question). However, during the middle third of the questions, where buzzes in Quizbowl most frequently occur, the accuracy on original test questions rises significantly quicker than the adversarially-authored ones. For both type of questions, the accuracy rises towards the end as the clues become “give-aways”.

5.2 Second Round Attacks: RNN Adversarial Questions are Brittle
In the second round, the authors also attack an RNN model. All models tested in the second round are trained on a larger dataset (Section 3.2).

A similar trend holds for IR adversarial questions in the second round (Figure 5): a question that tricks the IR system also fools the two neural models (i.e., adversarial examples transfer). For example, the DAN model was never targeted but had substantial accuracy decreases in both rounds.

However, this does not hold for questions written adversarially against the RNN model. On these questions, the neural models struggle but the IR model is largely unaffected (Figure 5, right).

5.3 Humans vs. Computer, Live!
In the offline setting (i.e., no pressure to “buzz” before an opponent) models demonstrably struggle on the adversarial questions. But, what happens in standard Quizbowl: live, head-to-head games?

We run two live humans vs. computer matches. The first match uses IR adversarial questions in a forty question, tossup-only Quizbowl format. We pit a human team of national-level Quizbowl players against the Studio Ousia model (Yamada et al., 2018), the current state-of-the-art Quizbowl system. The model combines neural, IR, and knowledge graph components (details in Appendix B), and won the 2017 NIPS shared task, defeating a team of expert humans 475–200 on regular Quizbowl test questions. Although the team at our live event was comparable to the NIPS 2017 team, the tables were turned: the human team won handedly 300–30.

Our second live event is significantly larger: seven human teams play against models on over 400 questions written adversarially against the RNN model. The human teams range in ability from high school Quizbowl players to national-level teams...
Figure 6: Humans find adversarially-authored question about as difficult as normal questions: rusty weekend warriors (Intermediate), active players (Expert), or the best trivia players in the world (National).

Figure 7: The accuracy of the state-of-the-art Studio Ousia model degrades on the adversarially-authored questions despite never being directly targeted. This verifies that our findings generalize beyond the RNN and IR models.

6 What Makes Adversarially-authored Questions Hard?

This section analyzes the adversarially-authored questions to identify the source of their difficulty.

6.1 Quantitative Differences in Questions

One possible source of difficulty is data scarcity: the answers to adversarial questions rarely appear in the training set. However, this is not the case; the mean number of training examples per answer (e.g., George Washington) is 14.9 for the adversarial questions versus 16.9 for the regular test data.

Another explanation for question difficulty is limited “overlap” with the training data, i.e., models cannot match $n$-grams from the training clues. We measure the proportion of test $n$-grams that also appear in training questions with the same answer (Table 2). The overlap is roughly equal for unigrams but surprisingly higher for adversarial questions’ bigrams. The adversarial questions are also shorter and have fewer NEs. However, the proportion of named entities is roughly equivalent.

One difference between the questions written against the IR system and the ones written against the RNN model is the drop in NEs. The decrease in NEs is higher for IR adversarial questions, which may explain their generalization: the RNN is more sensitive to changes in phrasing, while the IR system is more sensitive to specific words.

6.2 Categorizing Adversarial Phenomena

We next qualitatively analyze adversarially-authored questions. We manually inspect the author edit logs, classifying questions into six different phenomena in two broad categories (Table 3) from a random sample of 100 questions, double counting questions into multiple phenomena when applicable.
### Table 2: The adversarially-authored questions have similar n-gram overlap to the regular test questions. However, the overlap of the named entities (NE) decreases for IR Adversarial questions.

6.2.1 Adversarial Category 1: Reasoning

The first question category requires reasoning about known clues (Table 4).

**Composing Seen Clues:** These questions provide entities with a first-order relationship to the correct answer. The system must triangulate the correct answer by “filling in the blank.” For example, the first question of Table 4 names the place of death of Tecumseh. The training data contains a question about his death reading “though stiff fighting came from their Native American allies under Tecumseh, who died at this battle” (The Battle of the Thames). The system must connect these two clues to answer.

**Logic & Calculations:** These questions require mathematical or logical operators. For example, the training data contains a clue about the Battle of Thermopylae: “King Leonidas and 300 Spartans died at the hands of the Persians”. The second question in Table 4 requires adding 150 to the number of Spartans.

**Multi-Step Reasoning:** This question type requires multiple reasoning steps between entities. For example, the last question of Table 4 requires a reasoning step from the “I Have A Dream” speech to the Lincoln Memorial and then another reasoning step to reach Abraham Lincoln.

6.2.2 Adversarial Category 2: Distracting Clues

The second category consists of circumlocutory clues (Table 5).

**Paraphrases:** A common adversarial modification is to paraphrase clues to remove exact n-gram matches from the training data. This renders our IR system useless but also hurts the neural models. Many of the adversarial paraphrases go beyond syntax-only changes (e.g., the first row of Table 5).

**Entity Type Distractors:** Whether explicit or implicit in a model, one key component for QA is determining the answer type of the question. Authors take advantage of this by providing clues that cause the model to select the wrong answer type. For example, in the second question of Table 5, the “lead-in” clue implies the answer may be an actor. The RNN model answers Don Cheadle in response despite previously seeing the Bill Clinton “playing a saxophone” clue in the training data.

**Novel Clues:** Some adversarially-authored questions are hard not because of phrasing or logic but because our models have not seen these clues. These questions are easy to create: users can add Novel Clues that—because they are not uniquely associated with an answer—confuse the models. While not as linguistically interesting, novel clues are not captured by Wikipedia or Quizbowl data, thus improving the dataset’s diversity. For example, adding clues about literary criticism (Hardwick, 1967; Watson, 1996) to a question about Lillian Hellman’s The Little Foxes: “Ritchie Watson commended this play’s historical accuracy for getting the price for a dozen eggs right—ten cents—to defend against Elizabeth Hardwick’s contention that it was a sentimental history.” Novel clues create an incentive for models to use information beyond past questions and Wikipedia.

Novel clues have different effects on IR and neural models: while IR models largely ignore them, novel clues can lead neural models astray. For example, on a question about Tiananmen Square, the RNN model buzzes on the clue “World Economic
This man, who died at the Battle of the Thames, experienced a setback when his brother Tenskwatawa’s influence over their tribe began to fade.

This number is one hundred fifty more than the number of Spartans at Thermopylae.

A building dedicated to this man was the site of the “I Have A Dream” speech.

Table 4: The first category of adversarially-authored questions consists of examples that require reasoning. Answer displays the correct answer (all models were incorrect). For these examples, connecting the training and adversarially-authored clues is simple for humans but difficult for models.

Table 5: The second category of adversarial questions consists of clues that are present in the training data but are written in a distracting manner. Training shows relevant snippets from the training data. Prediction displays the RNN model’s answer prediction (always correct on Training, always incorrect on Adversarial).

Herald”. However, adding a novel clue about “the history of shaving” renders the brittle RNN unable to buzz on the “World Economic Herald” clue that it was able to recognize before. This helps to explain why adversarially-authored questions written against the RNN do not stump IR models.

7 How Do Interpretations Help?

This section explores how model interpretations help to guide adversarial authors. We analyze the question edit log, which reflects how authors modify questions given a model interpretation.

A direct edit of the highlighted words often creates an adversarial example (e.g., Figure 8). Figure 9 shows a more intricate example. The left plot shows the Question Length, as well as the position where the model is first correct (Buzzing Position, lower is better). We show two adversarial edits. In the first (1), the author removes the first sentence of the question, which makes the question easier for the model (buzz position decreases). The author counters this in the second edit (2), where they use the interpretation to craft a targeted modification which breaks the IR model.

However, models are not always this brittle. In Figure 10 (Appendix C), the interpretation fails to aid an adversarial attack against the RNN model. At each step, the author uses the highlighted words as a guide to edit targeted portions of the question yet
fails to trick the model. The author gives up and submits their relatively non-adversarial question.

7.1 Interviews With Adversarial Authors

We also interview the adversarial authors who attended our live events. Multiple authors agree that identifying oft-repeated “stock” clues was the interface’s most useful feature. As one author explained, “There were clues which I did not think were stock clues but were later revealed to be”. In particular, the author’s question about the Congress of Vienna used a clue about “Kraków becoming a free city”, which the model immediately recognized.

Another interviewee was Jordan Brownstein, a national Quizbowl champion and one of the best active players, who felt that computer opponents were better at questions that contained direct references to battles or poetry. He also explained how the different writing styles used by each Quizbowl author increases the difficulty of questions for computers. The interface’s evidence panel allows authors to read existing clues which encourages these unique stylistic choices.

8 Related Work

New datasets often allow for a finer-grained analysis of a linguistic phenomenon, task, or genre. The LAMBADA dataset (Paperno et al., 2016) tests a model’s understanding of the broad contexts present in book passages, while the Natural Questions corpus (Kwiatkowski et al., 2019) combs Wikipedia for answers to questions that users trust search engines to answer (Oeldorf-Hirsch et al., 2014). Other work focuses on natural language inference, where challenge examples highlight model failures (Wang et al., 2019; Glockner et al., 2018; Naik et al., 2018). Our work is unique in that we use human adversaries to expose model weaknesses, which provides a diverse set of phenomena (from paraphrases to multi-hop reasoning) that models cannot solve.

Other work puts an adversary in the data annotation or postprocessing loop. For instance, Dua et al. (2019) and Zhang et al. (2018) filter out easy questions using a baseline QA model, while Zellers et al. (2018) use stylistic classifiers to filter language inference examples. Rather than filtering out easy questions, we instead use human adversaries to generate hard ones. Similar to our work, Ettinger et al. (2017) use human adversaries. We extend their setting by providing humans with model interpretations to facilitate adversarial writing. Moreover, we have a ready-made audience of question writers to generate adversarial questions.

The collaborative adversarial writing process reflects the complementary abilities of humans and computers. For instance, “centaur” chess teams of both a human and a computer are often stronger than a human or computer alone (Case, 2018). In Starcraft, humans devise high-level “macro” strategies, while computers are superior at executing fast
and precise “micro” actions (Vinyals et al., 2017). In NLP, computers aid simultaneous human interpreters (He et al., 2016) at remembering forgotten information or translating unfamiliar words.

Finally, recent approaches to adversarial evaluation of NLP models (Section 2) typically target one phenomenon (e.g., syntactic modifications) and complement our human-in-the-loop approach.

9 Conclusion

One of the challenges of machine learning is knowing why systems fail. This work brings together two threads that attempt to answer this question: visualizations and adversarial examples. Visualizations underscore the capabilities of existing models, while adversarial examples—crafted with the ingenuity of human experts—show that these models are still far from matching human prowess.

Our experiments with both neural and IR methodologies show that QA models still struggle with synthesizing clues, handling distracting information, and adapting to unfamiliar data. Our adversarially-authored dataset is only the first of many iterations (Ruef et al., 2016): as models improve, future adversarially-authored datasets can elucidate the limitations of next-generation QA systems.

While we focus on QA, our procedure is applicable to other NLP settings where there is (1) a pool of talented authors who (2) write text with specific goals. Future research can look to craft adversarially-authored datasets for other NLP tasks that meet these criteria.

Acknowledgments

We thank all of the Quiz Bowl players, writers, and judges who helped make this work possible, especially Ophir Lifshitz and Daniel Jensen. We also thank the anonymous reviewers and members of the UMD “Feet Thinking” group for helpful comments. Finally, we would also like to thank Sameer Singh, Matt Gardner, Pranav Goel, Sudha Rao, Pouya Pezeshkpour, Zhengli Zhao, and Saif Mohammad for their useful feedback. german author of the sorrows of young werther and a two-part faust
german author of the sorrows of mr. werther

name this elegy on the death of john keats composed by percy shelley
name was this elegy on the death of percy shelley

identify this play about willy loman written by arthur miller
so you can identify this work of mr. miller

he employed marco polo and his father as ambassadors
he hired marco polo and his father as ambassadors

Table 6: Failure and success cases for SCPN. The model fails to create a valid paraphrase of the sentence for 97% of questions.

A Failure of Syntactically Controlled Paraphrase Networks

We apply the Syntactically Controlled Paraphrase Network (Iyyer et al., 2018, SCPN) to Quizbowl questions. The model operates on the sentence level and cannot paraphrase paragraphs. We thus feed in each sentence independently, ignoring possible breaks in coreference. The model does not correctly paraphrase most of the complex sentences present in Quizbowl questions. The paraphrases were rife with issues: ungrammatical, repetitive, or missing information.

To simplify the setting, we focus on paraphrasing the shortest sentence from each question (often the final clue). We analyze a random sample of 200 paraphrases: only six maintained all of the original information.

Table 6 shows common failure cases. One recurring issue is an inability to maintain the correct named entities after paraphrasing. In Quizbowl, maintaining entity information is vital for ensuring question validity. We were surprised by this failure because SCPN incorporates a copy mechanism.

B Studio Ousia Quizbowl Model

The Studio Ousia system works by aggregating scores from both a neural text classification model and an IR system. Additionally, it scores answers based on their match with the correct entity type (e.g., religious leader, government agency, etc.) predicted by a neural entity type classifier. The Studio Ousia system also uses data beyond Quizbowl questions and the text of Wikipedia pages, integrating entities from a knowledge graph and customized word vectors (Yamada et al., 2018).

C Failed Adversarial Attempt

Figure 10 shows a user’s failed attempt to break the neural Quizbowl model.

In his speeches this . . . As a Senator, this man supported Paraguay in the Chaco War, believing Bolivia was backed by Standard Oil.
this man’s campaign was endorsed by Milo Reno and Charles Coughlin.

Prediction: Huey Long (✓) → Huey Long (✓)

In his speeches this . . . As a Senator, this man’s campaign was endorsed by Milo Reno and Charles Coughlin, a Catholic priest and radio show host.

Prediction: Huey Long (✓) → Huey Long (✓)

Figure 10: A failed attempt to trick the neural model. The author modifies the question multiple times, replacing words suggested by the interpretation, but is unable to break the system.
